ACKNOWLEDGEMENTS

I am yet to locate words when this opportunity gives me unestimated pleasure to thank and divulge my headlong sense of gratitude to my guide, Dr. V. Subramanian, for suggesting me the problem and for his painstaking pointer, utilitarian exhortation, constructive criticism, unswerving encouragement and above all his scientific and humanitarian character has left an everlasting impression on the canvas of my mind.

Special thanks are due to the Dean, School of Environmental Sciences, for providing necessary facilities and University Grants Commission for extending financial assistance in the form of teacher-fellowship.

I am indebted to Mr. B.N. Mukhopadhyaya and Mr. Venu Gopalan Nair for conducting atomic absorption analysis, and to Mr. Sreevalson and Mr. Aswani for typing and illustrations.

My thanks are extended to friends and colleagues for their co-operation during this work.

I am most thankful to my parents and brothers for encouraging me during the course of my work.

To my wife, Mrs. Rita Singh, I owe more than I would care to admit.

SHAILENDRA KUMAR SINGH

ABSTRACT

Copper was coprecipitated with Fe and Mn as hydroxide at room temperature and pressure. The uptake and release of copper by hydrous Fe-Mn-oxide precipitate was investigated. The variables studied were pH, ionic strength and initial copper concentration.

The results indicate that the uptake of copper by hydrous Fe-Mn-oxide precipitate depends on the pH and the initial copper concentrations of the solution but is independent of the ionic strength of the media. As the initial copper concentration in the solution increases, the Cu uptake at lower pH values (< 3) increases.

The desorption experiments show that copper is present both as exchangeable and non-exchangeable "fixed" fraction in the coprecipitate. The relative proportions of these fractions in the precipitates vary with the ionic strength of the precipitating medium. In fresh water, the desorption is higher if the initial copper concentration is higher. Trace elements such as Co and Ni in the aqueous media can occupy these exchange sites.

Calculations based on solubility product data suggest that Cu does not precipitate as a separate copper phase and hence it will, somehow or other, be associated with the hydrous Fe-Mn-oxide precipitate.

The nature of the coprecipitate indicates the probability for it being a solid solution. This could not be confirmed because of the unavailability of IR and Mossbauer Spectra at the moment.

The experimental results can be used to explain the presence of heavy metals in natural ferromanganese materials. It can also be used for studies of pollution of the aquatic environment by trace metals.

INTRODUCTION

The behaviour of trace elements in natural aqueous system is attracting researchers because of environmental issues and yet this subject is not well understood. One of the first step in any systematic study of the aquatic chemistry of a potential contaminant is an elucidation of the principal modes of transport and reservoirs for the contaminant. For heavy metal contaminants such as Co, Cd, Pb, Zn, Ni, Hg, Fe and Mn, the hydrous oxides of Al, Fe and Mn may play dominant roles in determining reservoirs and modes of transport of these metals.

While the role of clays and biota in affecting the transport of radionuclides and other pollutants is commonly recognised, the significance of Fe and Mn among the factors that are involved is frequently overlooked. Cation exchange capacities of sea water and fresh water sediments are in the range of 30-60 meq/100 gm. It has been shown by Goldberg (1954) that the amounts of trace elements in sea water sediments are proportional to the iron or manganese content of the sediments. The observations by Morliner (1941, 1942), Hatchinson (1957) and others that oxidised sediments have much greater adsorptive powers than reduced sediments lend support to the idea that Fe and Mn play a significant role in influencing the distribution

and the transport of a variety of metal ions of both the naturally occurring and polluted kinds.

It has been known for a long time, that metal ion hydrolysis species are strongly adsorbed at solid-solution interfaces (Stumm & Morgan, 1962). This tendency to be adsorbed is especially pronounced for polynuclear poly hydroxo species. No adequate theory for this enhanced adsorption by hydrolysis is available, but few qualitative reasons can be:

- a) Hydrolyzed species are larger and less hydrated than non-hydrolysed species,
- b) The enhancement of adsorption is apparently due to the presence of a coordinated OH^- group.

Simple OH^- ions are bound at many solid surfaces and are frequently potential determining ions, hydroxo metal complexes may similarly or to an even larger extent be adsorbed to the solid surface (O'Hallia and Stumm, 1967). Finally, adsorption becomes especially pronounced for poly hydroxo-poly metal species because more than one hydroxide group "per molecule" can become attached at the interface. Most species containing OH^- -groups, cationic as well as anionic hydroxo-complexes, have been observed to be adsorbed at solid-solution interfaces.

It is interesting that adsorption of poly hydroxo metal complexes can occur against electrostatic repulsive forces, i.e.,

the chemical adsorption energy can outweigh the electrochemical work involved in the adsorption.

Co-agulation as practiced in water treatment is brought about by metal ion hydrolysis species and not by free multivalent metal ions (Matijevic et. al., 1961). These hydrolysis species also can play a significant role in flotation processes.

Considerable emphasis has been placed thus far on hydroxo-complexes; this is amply justified by the omnipresence of OH^- in water and by the strong affinity of many metal ions to OH^- ions.

OH^- ligand is selected over others because metal ions in solution in natural waters are not appreciably complexed by ligands other than H_2O or OH^- due to the fact that most bases indigenous to natural waters are unidentate ligands. And unidentate ligands form less stable complexes than multidentate ligands, especially in dilute solutions. And also in natural waters the concentrations of the ligands and the affinity of the ligands to the metal ion, with the exception of H_2O and OH^- , are usually sufficiently small so that at best a one ligand complex may be formed.

The role of metal hydroxides coatings in controlling trace element chemistry in fresh water environments has been investigated primarily by soil chemists. Coatings can be formed in two ways: while the hydroxides are precipitated, suspended grains offer a nucleus for coating; or, the negatively charged suspended clay surfaces attract the positively charged hydroxide ions to form coatings. Metallic coatings are generally 10% to 20% of the sediment grains by weight and seldom cover more than 40% of the grain surface (Sumner, 1964). The ability of the metallic hydroxide coatings to act as sinks for various trace metals is well known (Turekian & Scott, 1969; Jenne, 1968; Kharkar et. al., 1968; Gibbs, 1973; Martin et. al., 1973); these sinks are comparable to the ferro-manganese nodules in marine environment. These hydroxides and oxides readily sorb or coprecipitate cations and anions; even a low percentage of $\text{Fe}(\text{OH})_3$ and MnO_2 has a controlling influence on the heavy metal distribution in an aquatic system. Practical application of the sorption ability of hydrous metal oxides has been made in water and waste water treatment, particularly by the use of iron and aluminium salts for the removal of phosphorous compounds, organic contaminants and heavy metals. Under reducing conditions the sorbed heavy metals are readily mobilised; accumulations of hydrous Fe/Mn oxides can therefore act as a major source of dissolved metals in natural waters. The latter mechanism is particularly

effective in the presence of higher concentrations of dissolved organic material. The chemistry of Fe and Mn in natural aqueous systems have been studied in detail by Hem and Crooper (1959); Hem (1972) and Stumm & Morgan (1970).

While studies of hydroxides in fresh water systems are relatively few, hydroxide concretions have been studied in considerable detail in marine environments (Goldberg, 1954; Manhin, 1965; Cronan, 1969; Glasby, 1971). Hydroxide complexes in lakes have been studied by Dean (1970); Cronan (1972) and, in some mine drainage, by Dyck (1971).

Fe is the dominant trace element in natural aqueous systems; Mn is the next most important element - its chemistry is closely related to that of Fe (Krauskopf, 1957); Cu is considered in the present study as an example of other (minor) trace element. In coatings and other ferromanganese materials, significant quantities of Fe and Mn occur as hydroxides (Gibbs, 1973). In order to understand the behaviour of Fe, Mn and Cu in hydroxide precipitates, laboratory experiments were performed which involved the coprecipitation of hydroxides of Fe, Mn and Cu and the study of the properties of the aqueous media and also of the precipitates.

Previous Work

Fe and Mn have a mutual catalytic effect in the co-precipitation of their hydroxides (Hem, 1963; Morgan & Stumm, 1965). It is known through the works of Krusbain and Garrels (1952), Garrels and Christ (1965), Stumm and Morgan (1965), Langmuir and Whitmore (1971) and Subramanian (1973) that the pH is primarily the potential determining factor for hydrous oxide precipitates. The uptake of metals by hydrous oxide precipitates has also been found to be strongly dependent on pH (Murray et. al. 1968; Anderson et. al. 1973; Guy et. al. 1975; Loganathan et. al. 1977; Davis and Leckie, 1978). It could then be expected that partitioning of Fe, Mn and Cu between river water and Fe-Mn precipitate would also be influenced by pH. The chemistry of Fe, Mn and Cu in natural water systems can be considered in three parts: the dissolved phase, water-precipitate interaction and the inter elemental relationship within the solid precipitate.

River Water Characteristics

Wegenann, R. (1978) has summarized the data for average concentrations ($\mu\text{g/l}$) in different fresh waters and estimated "typical" fresh water concentrations of some trace metals (total (dissolved) (Table 1). Zirino, A. et. al. (1978) measured dissolved Cu in San Diego Bay and found copper concentration less than $0.1 \mu\text{g/l}$ at the mouth of the bay and increased toward the centre

of the bay to approximately 2.5 $\mu\text{g/l}$. Andrew Eaton (1979) reported that dissolved Cu concentrations in estuaries varies from the values as low as 1 $\mu\text{g/kg}$ to as high as 37 $\mu\text{g/kg}$ (Tees). Goldberg (1954) has cited the data for Fe, Mn and Cu concentration in sea water and manganese nodules (Table 2).

Due to their low solubilities, the hydroxides of the transition elements are precipitated from the river water when even a small change in the composition of the solution occurs. This will leave an insignificant amount of Fe, Mn and Cu in solution in the river water. Because of the importance of hydroxide ligand in these precipitates, pH (related to the concentration of hydroxyl ions in solution) should be related to the amount of Fe, Mn and Cu in solution.

Data for total dissolved Fe and pH were collected from several publications. The analyses were representative at several fresh water environments. The above data were combined in a single plot involving pH and total dissolved Fe and the plot is shown in Fig. 1. A negative relationship between pH and Fe concentrations is seen although there is scatter in the data. The scatter could reflect analytical errors or be an inherent relationship between the two variables. Gibbs (1972) has shown the effect of salinity on the concentration of major ions in

Table 1: Concentrations of Fe, Mn and Cu in some fresh waters.

Location	(µg/l)		
	Fe	Mn	Cu
North West Territories (NWT) Rivers, Canada	260	56	8
Lake Ontario	5	0.5	6

Rivers and Lakes of the U.S.A.	52	56	15
Large rivers of North America	300	20	5
Typical fresh water values	30	20	7

(Typical values are a compromise between different concentrations for different fresh waters.)

Table 2: Fe, Mn & Cu in sea water and Mn-nodules.

Metal	Weight per cent in Mn-nodules	Abundance in sea water (µg/l)
Fe	6.18 - 20.27	10 - 100
Mn	10.8 - 24.15	1 - 10
Cu	0.17 - 1.81	4

river water. With this help a plot of salinity vs pH for the same points were made (Fig. 2). The total dissolved Fe was now normalised by dividing with salinity and this ratio (Fe/salinity) was plotted against pH as shown in Fig. 3. A good negative correlation is evident which suggests the importance of ionic strength and pH in controlling the conc. of Fe in natural waters. So it can be expected that these can also be important variables for controlling Mn and Cu in natural waters.

Andrew Eaton (1979), from the studies of the San Francisco Bay estuary, indicated that the behaviour of Fe and Cu may be related.

Water - Precipitate Interaction

The understanding of exchange processes occurring at the sediment-water interface is important in the transport of heavy metals. The sediment is a complex mixture, with four main components: silica, clays, organic matter, and oxides of iron and manganese. The association of heavy metals with sediments can range from weak Vander Waals forces to strong covalent bonding, coprecipitation with ferromanganese oxides, and incorporation within crystal lattices. The release of sorbed heavy metals into the bulk water is dependent on partition coefficients, which in turn are related to sediment characteristics, the type of heavy metal, and other environmental parameters. As several of the

AND PH FOR VARIOUS RIVERS.

Fig. 3

INFLUENCES OF SALINITY ON THE pH AND TOTAL DISSOLVED Fe RELATIONSHIP.

metals concerned are potentially toxic pollutants, much interest is concerned with the chemical-composition of the sediment-water interface. At this boundary several chemical and biochemical transformation reactions occur, involving fluxes of mobile constituents from the sediment to the water (Lu and Chen, 1977).

Goldberg (1954) has given some data on the partition coefficients of some elements in marine waters. For Fe, maximum ionic concentration is 0.5 $\mu\text{g}/\text{l}$ and particulate concentration range is 1 to 100 $\mu\text{g}/\text{l}$, so the partition coefficient for Fe will be 2-200. Ionic Cu amounts to around 4 $\mu\text{g}/\text{l}$. The Cu adsorbed to Mn, which contains about one-thirtieth of its weight in Cu, would be 0.03 - 0.30 $\mu\text{g}/\text{l}$. So the partition coefficient for Cu is 0.01 to 0.1. The partition coefficient of Mn is 0.7.

De Groot et. al. (1973) calculated the discharge of heavy metals by the water and by the suspended matter of the Rhine and the ratios metal in water /metal in sediments (Table 3) and concluded that Cu will be present mostly in the suspended material. So the transport of these metals mainly takes place in a solid form.

Similar results have been found by Gibbs (1973) for the Amazon and Yukon rivers, where the ratios were even more extreme. Some observations from Strakhov's (1965) data and that of Cronan (1972) can be summarized as follows:

Table 3: Discharge of heavy metals by the water and by the suspended matter of the Rhine.

Metal	In the water (tons/yr)	Fixed to sediments fraction 16 um (tons/yr)	Metal in water/Metal in sediments
Pb	695	1830	1:2.6
Cr	1250	2820	1:2.3
Cu	765	1355	1:1.8
Zn	11380	6705	1:0.6

<u>Variables</u>	<u>Correlation Coefficients</u>
Dissolved Fe-Dissolved Mn	- 0.7632 (Data from Strakhov)
Dissolved Fe-pH	- 0.7551 (-do-)
Fe-Mn in suspension	- 0.5784 (-do-)
Fe-Mn in coatings	- 0.989 (Data from Cronan)

Ramamoorthy, S and Rust, B.R. (1978) observed that for a given heavy metal, the partition coefficient between sediment and solution is not greatly changed by the presence of another cation, provided the latter has the same order of concentration. If the concentration of one cation exceeds another by more than 10, however, significant desorption of the less concentrated ion takes place on a mass action basis.

Natural hydroxides, Coatings and Concretions

Numerous studies of river, lakes, estuarine and marine sediments have shown that many trace metals are concentrated in sedimentary material in natural aquatic systems (Turekian & Scott, 1967; Bower et. al. 1978; Andrew Eaton, 1978/79; Ramamoorthy & Rust, 1978; Griggs, 1978; Hamilton - Taylor, 1979). Because Fe and Mn hydroxides are more common in nature (Jenne, 1968; Turekian & Scott, 1967; Gibbs, 1973), it is worthwhile to look into the data collected by other workers. Fresh water ferro-manganese rich materials have been reported by several workers

(Strakhov, 1965; Dean, 1970; Cronan and Thomas, 1972; Rossmann et. al., 1972; Martin et. al., 1973). Data of Cronan and Thomas, Martin et. al. and Strakhov represent wide ranges in Fe and Mn values. Their Fe and Mn analysis are plotted in Fig. 4. Since their data differ by several orders of magnitude and also for clarity, scales have been purposely omitted from the figure. It appears that Fe and Mn are negatively related; since the total analyses by these authors include other metals, the observed negative relationship is not due to Fe and Mn complementing each other; rather, certain genetic considerations concentrate Mn in Fe-deficient materials and vice-versa. Fixation of Mn by $\text{Fe}(\text{OH})_3$ and Fe by hydrous MnO_2 is one possible explanation of the above relationship. Covariance of Fe and Mn in natural waters, could in effect, reflect a common source for them, such as ferro-manganese nodules and hydroxide coatings in the drainage basin (Subramanian, 1975; Subramanian, 1976).

Since hydroxide coatings and concretions are commonly reported to contain other elements besides Fe and Mn, the total trace metal content has been plotted against the total (Fe+Mn) in Fig. 5. A positive relationship between the trace element content and the (Fe+Mn) content is observed. Several workers have shown the existence of positive or negative relationship involving Fe or Mn on one hand and trace metals on the other (Goldberg, 1954; Hawkes, 1965; Cronan and Thomas, 1972; Rossmann et. al., 1972).

Fig. 4
CONCENTRATION OF Fe Vs. CONCENTRATION
OF Mn IN FERROMANGANESE RICH MATERIALS

Fig. 5.
CONCENTRATION OF (Fe + Mn) Ve. CONCENTRATION
OF TRACE METALS IN FERROMANGANESE RICH MATERIALS.

This suggests the combined role of Fe and Mn in the trace element fixation phenomenon.

Andrew Eaton (1978/79) when analysing the trace elements in San Francisco Bay sediments obtained the following mean concentrations of trace metals (Table 4). He concluded from his experiment that Fe and grain size variations are more important in explaining variance of elemental concentration in this estuarine system than Mn is. This indicates that Fe is a much more important geochemical agent than Mn in this system.

The baseline concentration of Cu in the sediments of Windermere England is about 24 ppm whereas Fe and Mn are 5.9% and 1.45% respectively (John Hamilton-Taylor, 1979). From the leaching experiments he found that the concentrations of Cu associated with the resistate fraction is constant at all depths with mean of 13 ppm. Thus, even where the metals are at their base line levels, the labile fraction constitutes 50% of the Cu.

Skei and Pals (1979) analysed metals in the sediment from Rana fjord, Northern Norway and found the enrichment of metals in surface sediment. He attributed it partly to organic matter diagenesis and scavenging on to freshly precipitated manganese oxide and mainly to anthropogenic inputs of metals.

Collin Neal et. al. (1979) found that authigenic As in North Atlantic deep-sea sediments is associated with authigenic iron in the same proportion as in ferromanganese nodules. He

attributed it to the fact that As is scavenged from sea water by an iron-bearing phase present in both sediments and nodules.

On the basis of his experimental studies, Subramanian (1976) could explain the negative inter elemental relationship between Fe and Mn and also the positive relationship between (Fe + Mn) and the trace elements in natural ferromanganese materials.

Hydrous Fe-Mn-oxides Heavy Metal Associations

It has been reported that the concentrations of Co, Zn and other agriculturally important heavy metals in the soils are quite high in the hydrous manganese oxides (Taylor and Mackenzie, 1966; Taylor, 1968; Sauree and Langmuir, 1975). Also large amounts of Co, Ni, Cu and other heavy metals occur in manganese nodules in the ocean (Willis and Ahrens, 1962; Moro, 1965; Burns and Fuerstona, 1966; Barnes, 1967; Crexar and Barnes, 1974). Heavy metals are common constituents of nodules and other sediments in rivers, lakes, estuary and ocean (Krapf, 1956; Cronan, 1969/70; Cronan and Thomas, 1972; Griggs, 1978; Bower, 1978; Andrew Eaton, 1978/79; John Hamilton-Taylor, 1979).

Jenne (1968), in reviewing the available information on the controls on Mn, Fe, Co, Ni, Cu and Zn in soils, sediments and fresh water, concluded that the hydrous oxides of Mn and Fe were

the major control on these heavy metals in soils and freshwater sediments. Zn was scavenged from waters of the Fraser river estuary by hydroxides of Fe and Mn, but desorption occur in the lower estuary and ocean (Grieco and Fletcher, 1977). Iron hydroxide, along with detritus and clay, were largely responsible for trapping many metals in pre-delta areas of the Ando River (Monaco, 1977). A practical example from the Arctic areas of Canada showing the dominant role of Fe and Mn oxides in the distribution of trace metals in fluvial systems is described by Cameron and Co-workers (Cameron, 1974; Cameron and Ballantyne, 1975; and Jonasson, 1977).

The sorption of heavy metals on hydrous Mn and/or Fe-oxides has been reported by many researchers (Morgan and Stumm, 1964; Posselt et. al., 1968; Murray et. al., 1968; McKenzie, 1970; Anderson, et. al., 1973; Loganathan and Bureau, 1973; Lockwood and Chen, 1973; Guy et. al., 1975; Burns, 1976; Loganathan et. al., 1977; Inoue Y. and Munemori, N., 1979).

Loganathan and Bureau (1973), Subramanian (1975) and Burns (1976) proposed that heavy metal ions are structurally bound in hydrous oxide of Fe or/and Mn.

Murray et. al. (1968) reported that group one and two cations are strongly sorbed on manganese dioxide. They found that the sorption was independent of small pH changes at high

concentrations of the cations and was highly pH dependent at low concentrations of the cations. They propose that in dilute solutions, the adsorption occurs as counter ions in the diffuse double layer, while in the high concentration, the sorption occurs within the manganese lattice. They also reported that Ni^{2+} , Cu^{2+} and especially Co^{2+} exhibited marked specific adsorption on the MnO_2 .

The uptake of Co^{2+} , Zn^{2+} and Ca^{2+} by $\alpha\text{-MnO}_2$ at $24 \pm 0.5^\circ\text{C}$ as a function of pH and salt concentration was investigated by Loganathan, Durai, Furstenam (1977). At pH values < 5 , there is not much change in the sorption of these cations with increase in pH. At pH values above 6, there is an abrupt increase in the uptake of Co^{2+} and Zn^{2+} within narrow pH ranges which depend on the equilibrium concentrations of the metal ion whereas no such marked increase of Ca^{2+} sorption was found upto pH 9.2. They proposed that this type of sharp increase in sorption is due to specific adsorption and is related to hydroxylation of the metal ions.

Guy et. al. (1975) studied the sorption of $\text{Cu}(\text{II})$, $\text{Cd}(\text{II})$ and $\text{Zn}(\text{II})$ on to potassium bentonite, hydrous MnO_2 , and solid humic acid and found that Cu distribution depends on the pH of the suspension. Above pH 6, 50% of the copper is sorbed on to the particulates whereas the Cu in solution is in a complexed form;

between pH 6 and 3.8 the soluble Cu is distributed between organic complexes and "free" copper ion; between pH 4.2 to 2.5 copper is being desorbed from the particulates; and below pH 2.5 all the Cu is present in solution as "free" Cu ion.

Davis and Leckie (1978) investigated the adsorption of Cu(II) and Ag(I) on $\text{Fe}(\text{OH})_3$ (amorphous) as a function of pH. He took the dilute total metal concentrations typically found in natural waters and an intermediate ionic strength between the extremes of fresh waters and marine systems. They found that Cu(II) and Ag(I) adsorption increases from 0 to nearly 100% adsorbed within a narrow pH range. The adsorption edge for Cu(II) is in the pH range 5-6. They also studied the effect of adsorbed complexing ligands on trace metal uptake by $\text{Fe}(\text{OH})_3$ (am) and found that despite the large amount of organic material present at the surface in the pH range 4-6, Cu(II) uptake by $\text{Fe}(\text{OH})_3$ (amorphous) is not significantly affected by the addition of these ligands to the system or by 10^{-3}M added sulphate.

Experiments conducted by Kharkar et. al. (1968) on the adsorption of Co, Ag, Se, Cr and Mo on various mineral phases in distilled water, and on desorption of adsorbed metals in sea water show that where a trace metal is adsorbed from fresh water solution, it is always released - to a greater or lesser degree - upon contact with sea water due to displacement by Mg and Na ions.

An experimental study was performed by Rehtagi and Chen (1975) on the effects of sea water on the concentrations of trace metals in waste water particulates. Samples of primary effluents, digested sludge, and mixtures of primary and secondary effluents were obtained from the Hyperion Treatment plant of Los Angeles, California. In most cases, Cd, Cu, Ni, Pb and Zn were found to be released to a greater extent than the other metals. Cr, Fe and Mn were not released except in the case of digested sludge, in which 9% of Cr and 36% of Mn was released from solid phases. However, up to 96% of Cd was released from suspended particulates. At different dilution rates of waste water effluents and digested sludge with sea water, no significant difference in the release of Cd was observed. On the other hand, the dilution ratio seems to play an important role in the release of Ni and Zn from suspended particulates.

Thus the analysis of the previous work indicates that hydrous Fe and Mn oxide is an effective sink for trace metals. It also indicates the combined role of hydrous Fe and Mn-oxide in controlling heavy metals in natural waters. In all the previous works, either iron hydroxide or manganese oxide was used as adsorbant except Subramanian's (1973), who studied the combined role of Fe and Mn in the fixation of Ni.

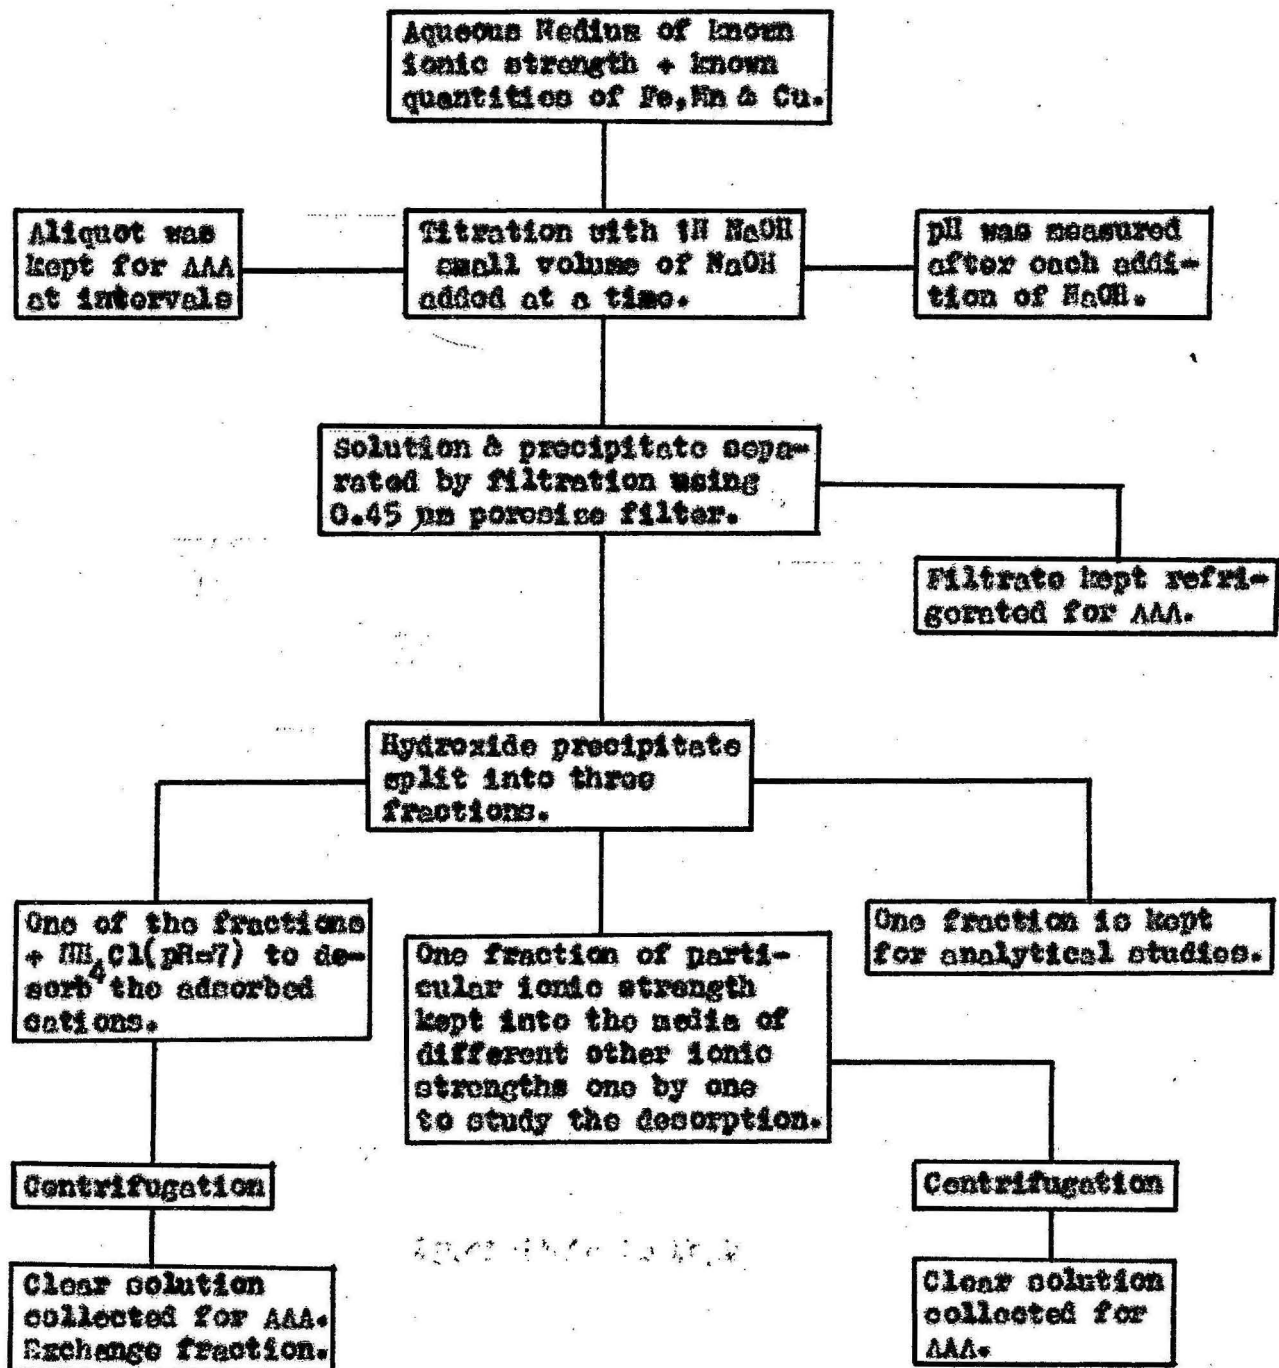

In the present work, an attempt is made to study the combined role of hydrous Fe & Mn oxide in controlling copper in the aquatic environment.

Description of Experimental Set Up

All analytical grade reagents were used. Aqueous NaCl solution having ionic strengths .01, .1, .3, .5 and .7 (ranging from river water to sea water) were prepared in the laboratory. Fe, Mn and Cu were added from stock solutions kept refrigerated in the amount required for individual experiments. Coprecipitation of hydroxides of Fe, Mn and Cu was effected by titrating the aqueous medium containing known quantities of Fe, Mn and Cu with NaOH. Desorption was done in a medium of 1 M NaCl solution adjusted to pH = 7.0. Desorption was also done by putting the precipitate of one ionic strength medium to the medium of different other ionic strengths one by one. Dissolved species were separated from solid suspensions or precipitates by filtration using 0.45 μ m pore size filter.

All experiments were done at room temperature and pressure. Elemental analyses were done with an IAS-1 model Atomic Absorption Spectrophotometer following procedures in its manual of instructions. Solutions of these species were acidified and kept refrigerated. pH measurements were done by a digital pH meter. The laboratory work is schematically illustrated in Fig. 6. Brief descriptions of individual experiments are as follows:

Fig. 6: A generalised flow-chart for the experimental work. (AAA - Atomic Absorption Analysis)

Coprecipitation Experiments

1. 100 cc of 200 ppm Fe, 100 cc of 200 ppm Mn and 100 cc of 100 ppm Cu were added simultaneously to 100 cc aqueous solutions of different ionic strengths (.01, .1, .3, .5 and .7) in different 500 cc pyrex beakers. Hydroxides were precipitated by titration with 1 N NaOH. After every addition of NaOH, pH of the solution was measured. Aliquots were kept at intervals for AAA. After complete precipitation, the solution and the precipitate were separated by filtration. The solution was kept refrigerated after acidification for elemental analysis. Desorption experiment was done with one portion of the precipitate and another portion kept for IR analysis.

2. 100 cc 200 ppm each of Fe and Mn and 100 cc of different concentrations of Cu (4 ppm, 20 ppm, 40 ppm, 60 ppm, 80 ppm, 120 ppm) were added in different beakers containing 100 cc aqueous solution of ionic strength 0.01. Coprecipitation, separation and analysis were done as above.

Desorption Experiments

1. In 1N NH_4Cl

A portion of the precipitate obtained from above experiments was suspended in 50 cc 1 N NH_4Cl maintained at pH 7 and kept for 1 hour. The aqueous portion was then separated and kept refrigerated after acidification for elemental analysis.

2. In different ionic strength media

Precipitate from one ionic strength media was suspended in 25 cc aqueous solution of different ionic strengths successively for an hour in each. The aliquot was then kept refrigerated after oxidation for elemental analysis.

Results and Discussions

Subramanian (1975) stated that adsorption is not pertinent to understanding the nature of Fe-Mn-hydroxide precipitate. It is not important whether adsorption or coprecipitation actually occurs in natural conditions because the inter elemental relationships within the hydroxide is not altered by the method of introducing Mn and Fe into $\text{Fe}(\text{OH})_3$. In this study, Fe, Mn and Cu have been coprecipitated as hydroxous oxide. In response to changes in pH, or other factors such as changes in total dissolved Fe, Mn and Cu in water, their hydroxous oxides would be precipitated from natural aqueous system.

In the present system anions present are OH^- , SO_4^{--} , NO_3^- and Cl^- . SO_4^{--} , NO_3^- and Cl^- will not affect the coprecipitation, as Cu (II) uptake by $\text{Fe}(\text{OH})_3$ (am.) is not significantly affected by sulphate ligand (Davis and Leckie, 1975), nitrate ion is a very weak complexing agent (Ramaswathy and Rust, 1978) and chloride is not an important complexing agent at room temperature. Above all, NaCl is used to represent different water bodies. To represent ocean system, Na^+ and Cl^- ions are very important. The solubility of OH^- is very low, so hydroxide will precipitate readily. Thus only OH^- ions are effective, others are not. Hence it may be assumed that the precipitate formed will be some form of hydroxous oxide.

In the case of coprecipitation, the mixture formed can be physical with the micro-component adhering to the surface of the major component or it can be structural with the microcomponent free to diffuse through the interior of the solid phase or it can be occlusion. Thus, coprecipitation can take place in a system of equilibrium or non-equilibrium involving miscible or immiscible components.

Jenno (1968), Allen et. al. (1970) have pointed out that the uptake or release of heavy metals from Fe and Mn oxides is a function of the type of heavy metal and its concentration, pH etc. The variables studied here are pH, ionic strength of the media and heavy metal concentration.

Here the results of uptake and release of copper by hydrous Fe-Mn-oxide precipitate are presented.

Uptake of Cu by Hydrous Fe-Mn-oxide Precipitate

In the laboratory experiment, Fe, Mn and Cu were completely precipitated as hydroxides. At that point, almost 100% of these go to solid phase irrespective of the ionic strength of the media in one case and different copper concentrations in the other (Table 5 and 6).

Fig. 7 shows the uptake of Cu(II) by hydrous Fe-Mn-oxide precipitate as a function of pH in different ionic strength media. The copper concentration is 25 ppm in all cases.

Table 5: % Uptake at different ionic strengths and same Cu concentration (25 ppm).

Ionic strength	Initial concentration in ppm			Final concentration in ppm			% uptake

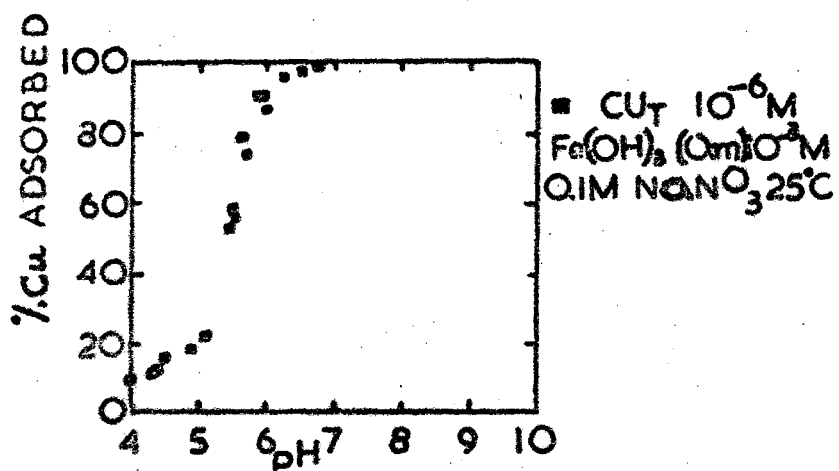

FIG. 7
Cu II UPTAKE BY Fe-Mn PPT AS A FUNCTION
OF PH AT DIFFERENT IONIC STRENGTHS

Similar to the results of many other investigations of hydrolysable metal ion adsorption (Schindler et. al., 1976; Guy et. al., 1975; Loganathan et. al., 1977; and Davis & Leckie, 1978), it is seen that most of the Cu (II) uptake takes place within a narrow pH range. The adsorption edge for Cu(II) is in the pH range 5.25 to 6.4 irrespective of the ionic strength of the media, which is approximately the same as observed by Davis and Leckie (1978) (Fig. 8) but in the present case about 48% Cu is sorbed at pH < 3 whereas sorption at lower pH is very small in Davis and Leckie's experiment. This may be due to the difference in different factors in the two experiments.

- 1) Adsorbent used by Davis & Leckie was $\text{Fe}(\text{OH})_3$ (amorphous) whereas in this case the adsorbent is hydrous Fe-Mn-oxide.
- 2) Concentration of copper used by him was very low, 10^{-6} M (i.e. 0.0655 ppm) whereas the concentration of copper in this experiment is 25 ppm. Second factor seems to be very strong for higher sorption of Cu at pH < 3 as is clear from Fig. 12 which shows that the sorption of Cu is zero at pH < 3 for lower copper concentration in the solution (here 1 ppm and 5 ppm) and it goes on increasing as the copper concentration in solution increases. For 30 ppm copper in solution, the sorption below pH 3 is about 52%. Using 10 $\mu\text{g}/\text{ml}$ copper, Guy et. al. (1975) found that sorption of copper on MnO_2 was zero below pH 1.5 (Fig.9). Both Fe and Mn oxide are present in the natural system, so the

FIG. 8

ADSORPTION OF COPPER (II) ON AMORPHOUS
 IRON OXIDE AS A FUNCTION OF pH

FIG. 9: COPPER SORPTION ON MnO_2
 AS A FUNCTION OF pH

present study is better representative of natural system than that of Guy et. al. (1975), Davis & Leckie (1978) and others because they have considered either only $\text{Fe}(\text{OH})_3$ or MnO_2 as adsorbant. Though this system deviates from the natural system, as the copper concentrations used are higher. But it can well represent a polluted natural system.

To know, whether the copper precipitated in the pH range studied is a separated copper phase or it is associated with the hydrous Fe-Mn-oxide phase, theoretical calculation was done at different pH to know the amount of copper which must be present in the solution in order to get the two probable solid copper compounds precipitates in this system: $\text{CuO}(s)$ and $\text{Cu}(\text{OH})_2(s)$. The calculations were done on the basis of solubility product data. Table 7 shows these values. Comparing this copper concentration value at particular pH with the copper concentrations present in the experimental system at that pH (Fig. 7), it is concluded that copper is not precipitated as a separate copper phase but somehow or other it is associated with hydrous Fe-Mn-oxide precipitate.

As the uptake of Cu takes place even at lower pH, it can be speculated that the surface charge of hydrous Fe-Mn-oxide precipitate is negative at all pH values studied, though surface charge is not determined in this study. Loganathan et. al. (1977) has reported that the surface charge of $\beta\text{-MnO}_2$ was

7.0	0.08763	0.635

*Corresponding, Cu^{+1} compounds, cuprous oxide and cuprous hydroxide are unstable in aqueous solution.

negative at all pH values, even at very low pH. Metal ions can then interact with the negatively charged particle in two ways:

- i) formation of a counter-ion layer.
- ii) specific sorption of ions on to the surface, as shown for copper sorption on to MnO_2 surface by Guy et. al. (1977).

It is also likely that adsorbed CuOH^+ is the predominant Cu(II) surface species, since it has been shown that adsorption of metal ions on various oxide surfaces increases abruptly in

the pH range where hydrolysis products become a significant fraction of the dissolved metal (Leckie and James, 1975).

Fig. 10 relates the uptake of Mn to pH which shows that about 50% Mn is coprecipitated at pH < 2.5, then there is almost no increase in Mn uptake till pH 6.95 and again there is abrupt increase in the uptake within narrow pH range (6.95 - 7.55). The uptake of Fe increases with increasing pH till pH 5.25 where the sorption is almost 100% (Fig. 11).

So the Figs. 7, 10 and 11 indicate that at higher pH, there is competition between Mn and Cu for $\text{Fe}(\text{OH})_3$ but copper is preferred by Fe over Mn.

Fig. 12 relates the uptake of copper by hydrous Fe-Mn-oxide precipitate to pH at different copper concentrations. The nature of the plot is very much the same as it is in Fig. 7 except the plot of 1 ppm Cu. This may be due to less number of data points taken in the experiment. But one thing is very clear from the Figure that as the concentration of Cu(II) in solution increases, the % uptake of Cu by hydrous Fe-Mn-oxide precipitate at lower pH also increases. The Cu uptake is zero below pH 2.75 when the Cu(II) concentration in solution is 1 ppm and 5 ppm, whereas Cu uptake is about 18% at pH 2.75 when the Cu concentration is 10 ppm, 25% when Cu concentration is 15 ppm, 36.5% when Cu concentration is 20 ppm and 52% when

FIG. 10
Mn UPTAKE AS A FUNCTION OF PH

FIG II
Fe UPTAKE AS A FUNCTION OF PH

FIG. 12

Cu(II) UPTAKE BY Fe-Mn-PPT. AS A FUNCTION OF PH
AT DIFFERENT Cu CONCENTRATIONS

the copper concentration is 30 ppm. In all concentrations, the Cu uptake increases with increasing pH.

Fig. 7 shows that the uptake of Cu by hydrous Fe-Mn-oxide precipitate is independent of the ionic strength of the media.

Now it can be inferred that pH and concentration of copper are important factors in controlling the sorption of Cu by hydrous Fe-Mn-oxide precipitate. It is also clear from above that copper is not precipitated in the system as separate Cu-phase but it is somehow associated with hydrous Fe-Mn-oxide. This association may be sorption, occlusion or/and solid-solution. Subramanian (1975) has proposed a solid solution model for Fe-Mn-Ni-hydroxide.

Sorption can be considered as an exchange reaction and is related to the structure of the host material. Chemisorption is generally reversible but may eventually lead to incorporation of minor elements (here Cu) in the structure of the host. On the other hand, coprecipitation of Fe-Mn-Cu hydroxide incorporates all of the above functions in a single step. Such a relationship between the trace metals and host materials may lead to occlusion or solid solution. Occlusion is a process in which the trace metals are locally distributed in the host so that the trace metal/host mixture cannot be considered as a single

homogeneous phase. In the case of a solid solution, the trace metals would be uniformly distributed over the host substance so that the precipitate could be considered as a single homogeneous substance.

Desorption is a method of determining the nature of the precipitated mixture within the framework of the above mechanisms. Desorbable cations from a precipitate are a measure of its exchange capacity. In addition a small amount of the precipitate will dissolve in the medium in which desorption takes place. Thus the precipitate loses its exchange fraction, and also the soluble fraction, to the aqueous media.

Release of Copper from the Precipitate

Fig. 15 and Table B relate the per cent release of Fe, Mn and Cu from the mixed precipitates obtained from solutions of different ionic strength media. The desorption experiment was done in 1 M NH_4Cl solution to show the exchangeable fraction of Fe, Mn and Cu in the precipitate. Figure shows that the desorption of Fe is negligible from all the precipitates formed from different ionic strength media, even the desorption of Mn is smaller. But the desorption of Cu is significant. The desorption of copper is around 40 to 47.5 % depending upon the ionic strength of the media. This shows the fraction of Cu in the exchangeable part of the precipitate. This desorption

FIG. 13
IONIC STRENGTH AS A FUNCTION
OF DESORBABLE Fe, Mn AND Cu IN
PRECIPITATES

Δ Fe ∇ Mn \circ Cu

might then represent the amount of Cu truly adsorbed, i.e., held on to the surface of hydrous Fe-Mn-oxide. Remaining amount of copper, which is more than 50%, must then be in the fixed portion of the precipitate, i.e., entered into the structure of the host. So this plot suggests that there is a large quantity of copper in the surface or exchange sites of the hydroxide precipitate and that most of the Mn and Fe are held together in the structure of the hydroxide. Thus the precipitates can be considered to contain two fractions - the exchangeable fraction and the non-desorbable "fixed" fraction. The relative proportions of these fractions in the precipitates vary with the ionic strength of the precipitating medium.

The presence of cations other than Fe, Mn and Cu in the coatings and other ferromanganese materials can be explained as follows: coprecipitated hydroxides contain some percentage of exchangeable fraction; the amount of this fraction varies depending on the ionic strength of the aqueous media. Cations such as Mn^{2+} , Co^{2+} and other compatible ions in the solution can replace the exchangeable Fe, Mn and Cu from the adsorption sites and thereby become part of the mass of the ferromanganese materials.

Initial copper concentration as a function of % copper desorption from the precipitates formed from solutions having

the same ionic strength (0.01, similar to a river water) is plotted in Fig. 14. The plot shows that the copper desorption increases with increasing initial copper concentration which is natural because copper will first enter into the structure of the Fe-Mn-oxide precipitate and then the excess copper will undergo surface adsorption. The Figure also shows a decrease in desorption when Cu is 50 ppm. This is inexplicable at the moment. It might be an analytical error.

Tables 8 and 9 show the percentage desorption of Fe, Mn and Cu under various experimental conditions. Precipitates formed from different ionic strength media having the same initial copper concentrations is desorbed into the media of another ionic strengths (Table 8). And precipitates having different initial copper concentrations formed from the same ionic strength (0.01) media is desorbed into different other ionic strength media (Table 9). In both the cases, the results show that the desorption of Fe, Mn and Cu is very small. Three values are higher, which might be due to analytical errors. So the desorption of Fe, Mn and Cu from the precipitates does not take place simply by change in media of the precipitate (i.e., river to estuary to sea) but it occurs when the compatible ions, like Mg^{2+} , Ca^{2+} etc. are present in the medium which can exchange with the exchangeable fraction of Fe^{2+} or Fe^{3+} , Mn^{2+} , and Cu^{2+} from the adsorption sites.

15	0.2	5.90	40.72.6		9.82	2.89	3.2	6.41	2	2.0	6.41	1.7	1.0	4.1	3.3
20	5.8	1.1	41	0.2	6.06	6.5	4.0	7.475	4.5	1.0	5.253	1.5	2.0	4.24	2.5
30	2.0	8.125	35.72.0		5.416	4.7	8.2	3.95	3.0	6.0	2.3	1.0	8.2	3.54	2.3

Thus the exchangeable fraction of the copper in the precipitate varies with the ionic strength of the media and the initial copper concentration in the solution.

Nature of the Precipitate

The nature of the precipitate formed by the coprecipitation of Fe-Mn-Cu-hydroxide can be viewed upon the basis of experimental results. Comparison of Figs. 7, 10 and 11 shows that the precipitation might be taking place in three phases when the concentration of Cu in the system is higher (25 ppm), i.e., approaching towards the concentration of major component Fe and Mn. First phase is below pH 3, where the hydrous Fe-Mn-Cu-oxide might be precipitating. The second phase is between pH 3 and 6.5, where the precipitate might be dominating in hydrous Fe-Cu-oxide. The third phase is above pH 6.5, ^{where} Mn might be precipitating alone as manganese oxide, because firstly, sufficient quantity of Mn (about 25 ppm) is still present there which is enough for manganese oxide precipitation and secondly Fe and Cu are completely precipitated below pH 6.5. It is already seen in this work that copper cannot precipitate as separate copper phase. So it suggests that Cu and Mn are in competition for $\text{Fe}(\text{OH})_3$ and Cu is preferred over Mn by $\text{Fe}(\text{OH})_3$. The ionic radii of Fe^{3+} is 0.64 Å, of Fe^{2+} is 0.74 Å, of Mn^{2+} is 0.60 Å and that of Cu^{2+} is 0.70 Å. The ionic radii value supports the fact that Fe prefers Cu than Mn.

On analyzing the plot of % Cu sorbed vs. pH for 1 ppm Cu, it can be speculated that in addition to the above probable precipitates, hydrous Mn-Cu-oxide precipitate is also possible.

The probable reactions of the precipitate formation can be:

If the iron be in the ferrous state, then the above reaction can be written as

Reactions between Fe-Cu and Mn-Cu can be as follows:

So the precipitate obtained may not be homogeneous. In sea water, Fe equilibrium is governed by systems such as $\text{FeOOH} - \text{Fe}(\text{OH})_2^+$ rather than $\text{Fe}^{+++} - \text{Fe}(\text{OH})_3$ (Kosior & Byrne, Jr., 1972).

Similarly for Mn and Cu, the equilibria may be $\text{MnOOH} - \text{Mn}^{++}$ and $\text{CuOOH} - \text{Cu}^{++}$. Hence the coprecipitated hydroxides may represent, particularly in high ionic strength, composition such as $(\text{Fe}, \text{Mn}, \text{Cu})\text{OOH}$.

Desorption experiments show that these mixed hydroxides have certain exchange capacity. Fig. 15 shows that Fe and Mn desorption is poor and Cu desorption is higher upto 47.4% at 0.3 ionic strength. This shows that copper is present both in "exchangeable" and the "fixed" fraction of the precipitate. If the desorption of Fe and Mn is compared, Mn is found to desorb much more than Fe in different ionic strength media. It again supports the fact that Mn might be precipitating in a separate phase as manganese oxide at pH above 6.5. Since mixed hydroxides have certain exchange capacity, cations such as Co, Cr etc. from the water can be adsorbed on to these sites, thus making the precipitate a chemically complex substance. Most ferro-manganese nodules and metallic hydroxide coatings represent such a complex system.

So the present results suggest that the coprecipitate might have different phases like hydrous Fe-Mn-Cu oxide, hydrous Fe-Cu-oxide and hydrous Mn-Cu-oxide. Any one or all of the phases might be dominating in the precipitate. Except some amounts of desorption observed, it may be said that each phase might be occlusion or solid solution. Whether it is occlusion or solid solution, it is iso-structural or non-isostructural, can be made known by IR and Mossbauer Spectra, which are yet to get.

Applications to Natural Systems

Both Fe and Mn are present in abundance in the natural system and their chemistry is closely related to each other (Krauskopf, 1957), so their hydrous oxides must be acting in combination in deciding the fate of trace metals in natural waters. Cronan (1972) found a positive relationship between (Fe + Mn) and the trace element content of hydroxide coatings and concretions which stresses the importance of combined role of Fe and Mn in the trace element fixation phenomenon. The present work studies the importance of hydrous Fe-Mn-oxide in the uptake and release of copper, hence it is more closer to the natural system than the study done by others (Guy et. al., 1975; Davies & Leckie, 1978), because they have either used manganese oxide or ferric hydroxide as adsorbant. Though the concentrations of copper in this study is higher which may represent a polluted system.

In natural suspended sediments, coatings are common because of electrostatic attraction between the negatively charged clay surface and the positively charged hydroxide solids. 10-20% by weight of the sediment could be the hydroxides. Although Fe and Mn can be coprecipitated as Fe-Mn hydroxides, they develop surface charges because of their finely divided nature. Generally, 40% of the particle surfaces are covered with coatings and the

excess negative charges in the particles would be satisfied only by successive layers of coatings. If the available positively charged hydroxide so is exceed that needed for coating formation, the excess so is may remain in colloidal suspension or attract anions such as HCO_3^- , Cl^- and SO_4^{2-} from the aqueous phase and form soluble or insoluble complexes. Thus, the coating process does not have to be a single-stage process. There could be successive homogeneous distribution of Fe, Mn and Cu in each layer but the overall coating process may be heterogeneous.

Though there are other sinks for Fe, Mn and Cu, such as oxide minerals and clay minerals, coating is the largest sink in natural aqueous system for these elements. Since they are transported along with the suspended sediments from rivers to oceans, the coatings can be considered as carriers of several elements from fresh water to saline water.

Coprecipitated Fe, Mn and Cu hydroxide can be considered as a natural hydroxide coatings, because Subramanian (1973) has pointed out that the experimental results in which the hydroxides were coprecipitated as coatings on suspended sediments does not differ with the results in which suspension was not used.

In aquatic systems where oxidizing occurs, hydrous iron and manganese oxides constitute a highly effective sink for heavy metals (Lee, 1975). Experiments by Groth (1971) show that the

metals Co, Zn and Cu coprecipitated from natural inland lake water with Fe/Mn hydroxides at a rate of 67%, 86% and 98% respectively. These findings are very much in conformity with the present finding for Cu.

Since the pH of river water does not vary appreciably in nature, coatings formed would be chemically stable as long as they remain suspended. Upon accumulation of suspension as bottom sediments, the pH and E_h of the environment changes from an oxidising environment to a reducing environment. Such a change may dissociate the coatings and release the elements, such as Fe, Mn and Cu, to the surrounding waters. Bonatti (1971), Cronan (1972) and Subramanian & d'Anglejan (1975) have shown that interstitial waters of bottom sediments are enriched in these elements. Of course, there are other sources, such as pyrite, for Fe in the reducing environment, but the coating can be a single source for several elements and only such an assumption can explain the generally high concentration of transition elements in interstitial waters of bottom sediments everywhere.

Experiments by Subramanian and Gibbs (1972) show that coatings act as inert but permeable membrane during exchange reactions. This is possible only if the hydroxide coating is structurally stable; the impurities (Mn and Cu) probably stabilise the hydroxides. The inert behaviour of coatings can then be thought of as suggesting that coatings are homogeneous multi-component phases, rather than simply Fe-hydroxide.

A remobilisation of heavy metals from suspended material and sediments is potentially hazardous not only for the aquatic ecosystem, but also for the drinking water supply. Remobilisation is mainly caused by four types of chemical changes in waters:

1. Elevated salt concentrations, whereby the alkali and alkaline earth cations can compete with the metal ions sorbed on to solid particles.
2. Lowering of pH which leads to dissolution of hydroxides, as well as to increased desorption of metal cations due to competition with H^+ ions.
3. Changes in the redox conditions, usually in conjunction with a decrease in the oxygen potential due to advanced eutrophication. Iron and manganese hydroxides are partly or completely dissolved, part of the incorporated or sorbed heavy metal load being released.
4. Increased use of natural and synthetic complexing agents, which can form soluble metal complexes sometimes of high stability with heavy metals that are otherwise adsorbed to solid particles.

In addition to these four processes, there are other biochemical transformation processes, by means of which heavy metals are either transferred from the sediment to animal or plant

organisms - possibly to be further enriched along the food chain - or are discharged directly or via decomposition products into water.

The present work studies the effect of elevated salt concentrations, increasing trace metal (Cu) concentration and pH on the remobilisation of heavy metals. Some amounts of desorption from the hydroxides take place in different ionic strength media, though some irregular pattern is there which may reflect the problem estuarine zone. At lower pH, Cu is desorbed completely when the copper concentration is lower. Since some amount of desorption from the hydroxides takes place, the exchange reaction can introduce Na, Mg and other cations into the coatings upon contact with a saline aqueous medium, such as sea water. The presence of cations other than Fe, Mn and Cu in the coatings and other ferromanganese materials can be explained as follows: coprecipitated hydroxides contain some percentage of exchangeable fraction; the amount of this fraction varies depending on the ionic strength of the aqueous media. Cations such as CO^{2+} , Zn^{2+} , Mg^{2+} , Na^+ ions etc. can replace the exchangeable Fe^{2+} , Mn^{2+} and Ni^{2+} from the adsorption sites and thereby become part of the mass of the ferromanganese materials.

Application to Pollution Studies

In addition to the natural inputs, anthropogenic inputs (like, industrial effluents, sewage disposal, agricultural runoff, mining activities etc.) are the major source of pollution of the aquatic environment. Among the pollutants, heavy metals is of grave concern. Sometimes, the establishment of metal levels in sediments can play a key role in detecting sources of pollution in aquatic systems. Metals such as Cr, Co, Ni, Cu, Zn, Cd, Hg and Pb have become enriched in sediments chiefly as a result of man's activities. Turekian and Scott (1967) were able to determine a distinct accumulation of Ag, Ni and Co in suspended material from eighteen rivers, particularly in the case of Susquehanna River, which they ascribed to industrial contamination. He concluded that "the annual transport of trace elements by the Susquehanna River as suspended material is sufficiently large to be of possible economic interest if the demand for some of the metals increases and the metals are present in an easily reversible form." De Groot and Allersma (1973) calculated the discharge of heavy metals by the water and by the suspended matter of Rhine. They found that 765 tons/year of Cu is discharged in water and 1355 tons/year fixed to sediments. So the metal in water to metal in sediments ratio come to 1:1.8. Hence the transport of Cu and any other

metal mainly takes place in solid form. Among other substances, sediment contains hydrous Fe and Mn oxides. So hydrous Fe and Mn oxide carries heavy metal with them in the solid form. Saures, D.L. and Langmuir, D. (1976) studied the soil samples from 70 ft. beneath a municipal waste land-fill in Central Pennsylvania and determined Mn, Fe, Ni, Co, Cu, Zn, Cd, Pb, and Ag in exchangeable and nonexchangeable forms. They found that heavy metals, Co, Ni, Pb, Zn, Cu, Cd, and Ag were associated with Fe and Mn oxides. It is in agreement with the present work that Cu uptake is very significant by hydrous Fe-Mn-oxide. The sorbed copper is desorbed depending upon the ionic strength of the media. The desorption increases with the increasing initial copper concentration.

Sitasawad, R.L. (1980) reported the metal content of Jamuna river water around Delhi (Table 10). Mn content of the river is almost zero. The Fe content of the river remains the same (0.36 ppm) both when Jamuna enters Delhi at Wazirabad and leaves at Okhala, irrespective of the fact that drains are contributing the metals to the river in between. This excess Fe then must have gone to the sediments, may be in the form of hydrous Fe-oxide. Cu concentration in the river has increased slightly at Okhala, obviously due to the contribution by drains. This does not agree with the proposed mechanism for the Cu uptake

Table 10: Average Metal Concentration in River Jamuna (in ppm)

S.No.	Cr ⁺⁶	Mn ⁺⁺	Pb ⁺⁺	Ni ⁺⁺	Cu ⁺⁺	Zn ⁺⁺	Pb ⁺⁺
1. Upstream of Najafgarh drain mixing at Wazirabad	0.40	0	0.56	1.05	0.078	0.16	0.25
2. Average concentration of metals in drains	0.39	0.028	0.37	0.59	0.064	0.22	0.35
3. Weighted discharge of average drains	0.0028	0.0002	0.0026	0.0042	0.0005	0.0016	0.0025
4. Expected concentration of metals if drains are polluting at Okhla	0.4028	0.0002	0.3626	0.0542	0.0385	0.1616	0.2525
5. Observed concentration of metals at Okhla	0.40	0.017	0.36	0.86	0.056	0.17	0.33

by Fe-Mn-precipitates in the present study. It may be due to the fact that Cu concentration even at Okhala is very small (0.056 ppm) which may be lower than the solubility product of any probable Cu compound in the system whereas the minimum Cu concentration used in the present study is 1 ppm. The proposed mechanism can be used to explain the decrease in Ni content of the river from 1.05 ppm at Wasirabad to 0.06 ppm at Okhala. So one possibility is that Ni might have gone to sediment in association with hydrous Fe-oxide. Ni uptake by hydrous Fe-Mn-oxide precipitate has been proposed by Subramanian (1973). Similarly the same concentration of Cr (0.40 ppm) at Wasirabad and Okhala inspite of the contribution by drains in between the two points can be explained on the basis of present study.

The present work represents the polluted environment more closely as the Cu concentration in the experiment is higher.

Limitations of the Experiment

Hydrous Fe-Mn-oxide is used in the present work to study the uptake and release of copper. Organics, clay minerals etc. are present in the natural system along with Fe/Mn hydroxide which can affect the sorption and desorption of heavy metals by Fe/Mn hydroxide. Moreover, inorganic and organic complexing ligands can increase or decrease the uptake of heavy metal by Fe-Mn hydroxides which are not considered here. The

artificial river, estuarine or sea water used in the present work approximates a world average composition, extension of the results to any specific sites should take into consideration local conditions.

Analyses of natural nodules and hydroxide coatings by various workers have shown the presence of several elements correlated to either Fe or Mn. It was shown earlier that Fe and Mn together can be correlated to all other elements taken together. This is possible because Fe-Mn together form a stable double hydroxide and this hydroxide adsorbs other elements or exchanges with aqueous medium.

Now it is evident that while there is no doubt that hydrous metal oxides are important sinks and modes of transport for heavy metals in the environment, the quantitative magnitude of this role cannot be estimated at the present stage for a variety of natural water conditions.

Thus, it can be stated here that within the limitations of experimental conditions, the observations made can be used to explain the nature of hydroxide coatings and their ability to fix trace metals.

Conclusions

The hydrous Fe-Mn-oxide can be an effective sink for copper in the aquatic environment. The results of uptake and release of copper can be concluded as follows:

- 1) pH and copper concentration are two important factors in controlling the Cu-uptake by the hydrous Fe-Mn-oxide precipitate. The Cu-uptake takes place within a narrow pH-range depending upon the concentration of Cu(II) in solution. The ionic strength of the media does not matter appreciably in the uptake.
- 2) Copper is not precipitated as a separate copper phase, rather it is associated with the hydrous Fe-Mn-oxide. The precipitate formed may be hydrous Fe-Mn-Cu-oxide, hydrous Fe-Cu-oxide and/or hydrous Mn-Cu-oxide.
- 3) Copper is present both in exchangeable and fixed fraction of the precipitate. Almost 50% of copper is fixed in the structure of the host. Whether this fixed fraction is uniformly distributed in the host or not, is not established in this work.
- 4) Release of copper from the host is not affected by simply changing the media of the precipitate, but it is the presence of exchangeable cation in the media which cause the release of copper from the precipitate.

5) The results can be used to explain the presence of heavy metals in natural ferromanganese materials. It can also be used for studies of pollution of the aquatic environment by trace metals.
